The title

Methods

Participants

In the American English validation study, the participants were 204 parents of children aged 15 to 36 months ($M = 26.21$, $Mdn = 26$, $SD = 6.37$). There were 103 girls in the sample (50.49%). The sample was ethnically diverse, including White, Black, Latino/Hispanic, Asian, Native American, and other races/ethnicities. None of the children were reported to hear other languages apart from English. The average number of years of education attained by the primary caregiver was 15.82 ($SD = 2.27$).

In the Polish validation study, the participants were 113 parents of children aged 18 to 34 months ($M = 24.73$, $Mdn = 24$, $SD = 4.47$). There were 49 girls in the sample (43.36%). The sample was White (reflecting the limited ethnic diversity within the Polish population). However, there were 28 children multilingual with Polish (as their home language) and some other (societal) language, living outside of Poland. Parents were asked about their education level and 65 reported having higher education or PhD, 1 reported having unfinished higher education, 11 reported having secondary education and 36 did not report their education level.

Notably, the two validation samples differed slightly (but significantly) in the mean age of children, $\Delta M = -1.49$, 95% CI $[-2.69, -0.28]$, $t(297.82) = -2.42$, $p = .016$, which may affect the outcomes of direct comparisons between the samples, where age could be a contributing factor. We present one such comparison—standard error of CAT ability—where this difference is explicitly discussed. *NOTE*: You can also view/comment on this on GitHub Issue #7 linked here.

39 **Materials**

40 The data was gathered with CAT-CDIs in American English and Polish. The
41 American English CAT-CDI was created from the items that were common to three CDIs:
42 Words and Gestures, Words and Sentences and CDI-III. With these items, two CAT-CDIs
43 were created, one for word production and another for word comprehension (see Kachergis
44 et al. 2022 for more details). The Polish CAT-CDIs were created following a largely similar
45 procedure as the ones in American English, but there was a separate CAT-CDI developed
46 for each CDI version (CDI: Words and Gestures and CDI: Words and Sentences) and for
47 each CDI:WG subscale (word production, word comprehension, gesture use) (Krajewski et
48 al. in preparation). The American English CAT-CDI word production included 679 items
49 and the Polish CAT-CDI version of WS: Words and Sentences included 666 items. There
50 are 395 words common to both CAT-CDI language versions.

51 **Procedure**

52 Though in both American and Polish validation studies the parents were asked to fill
53 in both the full CDI and the CAT-CDI, the procedure differed between the two studies. In
54 the validation of American English CAT-CDI, parents were given both CDIs in one sitting,
55 but the order of the CDI versions was counterbalanced. In the Polish validation study, the
56 order of the CDIs was fixed, with the full CDI always first, and then, after 1–30 days ($M =$
57 8.31, $Mdn = 8$, $SD = 4.90$) parents were asked to fill in the CAT-CDI. Both studies were
58 done fully online and obtained the approval of adequate ethics committees.

Results

Psychometric properties of the two CAT-CDIs

Our first aim was to examine whether CAT-CDIs in American English and Polish demonstrate comparable psychometric properties. To that end, we revisit the psychometric properties reported for the American English CAT-CDI (word production) in Kachergis et al. (2022) and compare those to the data from Polish CAT-CDI:Words and Sentences.

We found similarly strong correlations in the two languages between the abilities estimated from CAT-CDI and full CDI scores (English and Polish: $r = .86$). The correlations were also strong within individual age groups (see Tables 1 and 2). We also obtained IRT ability estimates from the full CDI using the same 2-PL model. Because these estimates draw on responses to all available items in the full CDI, they incorporate more information about each child's performance, reducing random error and increasing precision. The 2-PL model further adjusts for item difficulty and discrimination, making these ability scores robust and comparable across individuals. Such ability from the full test version is often considered a baseline for comparisons with ability estimated from a short (adaptive) version. We correlated the abilities estimated from the CAT-CDI and abilities estimated from full CDI and again found strong correlations in both languages, English and Polish: $r = .92$. Finally, we also correlated the abilities estimated from the full CDI and the full CDI scores, i.e. two measures obtained from the same data. This way we examine consistency between model-based abilities and traditional scores. Again, we found strong correlations in both languages (English: $r = .95$, Polish: $r = 0.94$), confirming that both measures reflect the same underlying ability.

Table 1

English: Correlations between ability estimated by CAT-CDI and ability estimated from full CDI by children's age.

	[15,18)	[18,21)	[21,24)	[24,27)	[27,30)	[30,33)	[33,36]
r ability CAT vs full CDI	0.95	0.85	0.82	0.83	0.59	0.84	0.86
N	26	22	26	30	28	24	48

Table 2

Polish: Correlations between ability estimated by CAT-CDI and ability estimated from full CDI by children's age.

	[15,18)	[18,21)	[21,24)	[24,27)	[27,30)	[30,33)	[33,36]
r ability CAT vs full CDI	NA	0.8	0.94	0.91	0.89	0.95	NA
N	NA	29	22	16	23	22	1

82

83 Next, we looked at the mean squared error (MSE) which quantifies the difference
84 between the abilities as estimated by CAT-CDI and the full CDI (for each participant, we
85 subtract the CAT-CDI estimate from the full estimate and square this difference to
86 eliminate negative values). The mean squared error in English was 0.57 ($Mdn = 0.35$, SD
87 $= 0.70$), and in Polish it was 0.19 ($Mdn = 0.08$, $SD = 0.45$). The MSE was relatively high
88 in English (compared to Polish), indicating a relatively larger discrepancy between
89 CAT-CDI ability estimates and full CDI ability estimates in English. This occurred despite
90 strong correlations between the two measures. This difference between the full and
91 CAT-CDI estimates may be explained by at least two reasons. First, a number of

participants with extreme discrepancies between the CAT-CDI and full CDI estimates may be inflating the MSE. Second, there might be a systematic bias, with one estimate consistently higher than the other.

To explore the first of these possibilities, we identified children for whom the estimates from the CAT-CDI and full CDI showed extreme discrepancies, i.e. the difference between the two estimates was removed by 1.5 SD from the mean. There were 15 such cases (7.35%) in the English dataset and 4 cases (1.96%) in the Polish dataset. We then re-calculated the mean squared error without these cases, which yielded an MSE of 0.44 ($Mdn = 0.29$, $SD = 0.44$) in English and 0.12 ($Mdn = 0.07$, $SD = 0.14$) in Polish. The updated MSE values were only slightly lower than the original ones, suggesting that extreme discrepancies had only a modest effect on the overall error and cannot fully account for the differences between ability estimates from the full CDI and the CAT-CDI in the two languages.

Next, we examined a possible bias in our two ability estimates. We found that the mean CAT ability estimates were higher than the full CDI ability estimates. That was true both in English, $M_D = 0.55$, 95% CI [0.48, 0.62], $t(203) = 15.11$, $p < .001$ (large effect size: Cohen's $d = 1.06$, 95% CI [0.89, 1.23]), and in Polish, $M_D = 0.26$, 95% CI [0.19, 0.32], $t(112) = 7.71$, $p < .001$ (medium effect size: Cohen's $d = 0.73$, 95% CI [0.52, 0.93]). A closer look showed that the difference between the full and CAT-CDI estimates depended on the child's ability level (see Figure 1). For low ability, the English CAT-CDI estimates tended to be higher than the full scores. For the highest ability, the estimates from the two CDIs seemed most aligned. In Polish, the CAT-CDI estimates generally aligned more closely with the full CDI estimates across the whole range of ability. Still, a similar trend has emerged as in English, though weaker: for the lowest ability levels, the CAT-CDI estimates were mostly higher than the full CDI estimates. However, for the highest ability levels, the CAT-CDI estimates were in fact lower than the full CDI estimates.

The question that remains is whether the differences between the two estimates of

Figure 1. The relation between ability (estimated from full CDI) and the size of discrepancy between the estimates from full CDI and CAT-CDI: (A) English, (B) Polish.

abilities come from CAT over-estimating child's true lexical ability or from the full CDI underestimating child's ability. For one, it may be that in CAT-CDI parents answer "yes, my child produces this word" to more items that would be expected (Kachergis et al. 2022), and as a result, CAT-CDI may overestimate the child's true ability. On the other hand, it could be that as the full CDI is very long, parents may omit marking some items that their child produces (see e.g., Łuniewska et al., 2025 for parental inconsistencies in reporting vocabulary of older children). This could result in the full CDI underestimating the child's true ability. It is possible that both are true and the question is difficult to answer without direct assessment of child's lexical ability. With the existing data, we can at least compare the precision of the two estimates to assess which measure is likely more reliable.

128

129 We looked at how precision of the estimate, measured by standard error of the theta
 130 (SE), related to the ability levels. In both languages, the characteristic U-shaped curves
 131 indicated that measurement precision was highest around the middle of the ability range
 132 (i.e., showing lowest SE) and declined at the extremes (very low or very high ability the SE
 133 values were the highest) (see Figure 2). This U-shape was observed for both the CAT-CDI
 134 and the full CDI, indicating that even the full CDI provides relatively less precise estimates
 135 at the extreme ends of ability.

Note that in English there is only one case where CAT estimate was smaller than -1.5, therefore no CAT boxplot is plotted in that bin.

Figure 2. The relation between ability estimates from full CDI and CAT-CDI and the standard error of that estimate: (A) English, (B) Polish.

136 In both CAT-CDIs, we have been able to reliably estimate lexical ability for majority
 137 of children. Taking as the cut-off Makransky's suggestion to consider an SE below 0.2 as

acceptable, such precision of the CAT-CDI estimate was obtained for 92.6% of the American participants, and 96.5% of the Polish participants. The remaining participants were at the extremes of the ability scale—children with either relatively low or relatively high lexical skills (see Figure ??). The ability estimates from the Polish CAT-CDI generally fell well below an SE of 0.2, except for the highest-ability observations, where precision was worse, but still similar to the precision of the full CDI. Because the Polish CAT-CDI was designed to stop once an SE of 0.1 was reached, the precision of Polish estimates never went below this threshold. Overall, the Polish CAT-CDI appears to provide precision comparable to the full CDI, particularly for children with relatively low abilities. This suggests the CAT-CDI is selecting items that are more informative at those lower ability levels.

Taken together, the results reported so far show that for the English CAT-CDI, the CAT-CDI estimates correlate strongly with both full CDI scores and estimates obtained from the full CDI. The CAT-CDI estimates are consistently higher than the full CDI and show slightly worse precision than the full CDI, however, for the large majority of children, the obtained CAT-CDI estimates were below the precision cut-off point of 0.2. In Polish, the CAT-CDI estimates also correlate strongly with both full CDI scores and estimates obtained from the full CDI. The CAT-CDI estimates are consistently higher than the full CDI, but this discrepancy is smaller than in English. The Polish CAT-CDI also yielded ability estimates with more similar precision as the full CDI, and importantly, for children with lower abilities, CAT-CDI was able to provide an estimate with the same precision as the full CDI. This might potentially suggest that for lower abilities, CAT does not over-estimate children's true abilities, however, more research needs to be done.

Item properties in the two CAT-CDIs

Our second aim was to analyze similarities and differences in IRT item properties in CAT in English and Polish.

There are 679 items in the English CAT-CDI and 666 items in the Polish CAT-CDI. In both languages, the items' difficulty and discrimination parameters were calculated using IRT 2 parameter model (these included separate samples, see Kachergis et al. 2022 and Krajewski et al., in preparation). An item's difficulty indicates the ability level at which there is a 50% probability that a participant will respond correctly (here: that a child will know a word). Difficulty is expressed on the same scale as theta (measured ability): negative values correspond to harder items, values near zero to items of moderate difficulty, and positive values to easier items (note that difficulty is inversely related to theta and so, negative theta means low ability while positive theta means high ability). An item's discrimination shows how well it can distinguish between individuals whose abilities are close. In this paper, we focus mainly on item difficulty, as it is directly tied to the ability being measured, whereas discrimination reflects more the quality of the item as a measurement tool.

English items were in general more difficult than the Polish items, $\Delta M = -1.87$, 95% CI $[-2.06, -1.69]$, $t(1227.61) = -20.09$, $p < .001$ (English: min = -7.16, max = 4.45, $M = -2.19$, $Mdn = -2.21$, $SD = 1.98$; Polish: min = -4.34, max = 4.41, $M = -0.32$, $Mdn = -0.43$, $SD = 1.41$). This was true also for a subset of 390 items common to both languages - English items still proved to be more difficult than the Polish ones: $M_D = -1.68$, 95% CI $[-1.82, -1.54]$, $t(389) = -23.11$, $p < .001$. This is a result of the characteristics of the samples used to estimate the item parameters. In English, item difficulty was calculated based on a broader sample of children aged 12–36 months, spanning the CDI:WG, CDI:WS, and CDI-III (reflecting the idea of having one CAT-CDI for all the age versions), whereas the Polish data came from a sample of narrower age range of 18–36 months, corresponding to the CDI:WS. As a result, item difficulty in English was estimated using a relatively younger sample, for whom certain items may have been more challenging – thus appearing more difficult – compared to the older Polish sample. Still the item difficulty for common items in the two languages was positively and moderately correlated: $r = .65$,

191 95% CI [.58, .70], $t(388) = 16.68$, $p < .001$.

192 We also examined whether CDI semantic categories show comparable difficulty values
 193 across the two languages. To this end, we conducted a series of Spearman's rank
 194 correlations on item difficulty within each semantic category (we considered only items
 195 common to both the Polish and English CDIs) (see Table 3). The rank correlations
 196 coefficients varied by category, but for half of the categories the correlations were moderate
 197 to strong (0.52 to 0.91).

198 The least correlated semantic category was Quantifiers. The discrepancy may be
 199 partially to the fact that many English quantifiers map onto multiple Polish equivalents -
 200 for example, "some" maps to two Polish CDI items, "jeszcze" (with a similar difficulty
 201 value as the English "some") and "więcej" (more difficult than "jeszcze" and "some").
 202 These two Polish items are used in different contexts, i.e., "jeszcze" would be used more
 203 often in child directed speech than "więcej" also because it can be used to refer to both
 204 quantity and repetitive actions (meaning "again"). "Więcej" implies a quantitative
 205 comparison of some sorts, as in "more than before" or "more than two".

206 Interestingly, the second least correlated semantic category were Clothes. Here, some
 207 divergence may be explained by one-to-multiple mapping (e.g., "hat" is either "czapka" or
 208 "kapelusz" in Polish), but also words characteristics, e.g., "bib" in Polish is a much more
 209 complex word, "śliniaczek"; English "underpants" are more morphologically complex (and
 210 maybe less frequent) than Polish "majtki".

211 Taken together, these two semantic categories reflect the existing cross-linguistic
 212 differences in lexical mapping as well as item-specific factors such as frequency,
 213 morphological complexity, and contextual usage that .

Table 3

Cross-linguistic correlations of item difficulty within each CDI semantic category (Spearman's rank correlations).

CDI category	rho	n
quantifiers	0.11	10
clothing	0.22	19

people	0.67	16
animals	0.68	29
toys	0.74	15
question_words	0.91	10

Last, we investigated whether particular lexical categories show related difficulty values across the two languages. We considered the following lexical classes: verbs, nouns, adjectives, function words and other, i.e. mostly sounds and words relating to routines (e.g. “hello”, “yes”, “thank you”) and time (e.g. “tomorrow”, “day”). Again, we performed a series of Spearman’s rank correlations (on the difficulty of items common to CDI-CATs in Polish and English) for each lexical class (see Table 4. The weakest correlation was for function words (0.40), then verbs (0.47), adjectives (0.53), nouns (0.6), other (0.75). Notably, function words include many of the CDI semantic categories which showed the lowest correlations in Table 3, i.e., quantifiers, connecting words, locations, and pronouns. Again, many English function words map onto multiple Polish equivalents, e.g., “which” corresponds to “jaki” (when asking about type, kind, or quality) and “który” (when selecting from a limited set of options). These cross-linguistic differences partially explain the weaker correlation for function words. What is more, because function words are structurally tied to grammar (which is highly language-specific) they naturally vary in frequency in child-directed speech and in their communicative salience, which can affect how well children know them across languages. By contrast, the relatively high correlations for nouns, sounds and words relating to routines (grouped together as “other”) reflect their consistent easiness/difficulty across languages: words such as “mum”, “ball”, “hi”, “woof woof” are acquired early, aligning with findings that nouns are strongly and consistently over-represented in early vocabularies across many languages (e.g., Frank et al., 2021).

Table 4

verbs	0.49	71
adjectives	0.53	25
nouns	0.59	194
other	0.75	50

CAT-CDIs’ usefullness in research and practice

We assume that, for a CAT-CDI to be useful in the contexts of research and practice (e.g., for screening or diagnosis), it should meet the following criteria:

1. Provide estimates with equal or lower standard error compared to the full CDI.
2. Maintain high precision (i.e., low standard error) across relevant levels of ability.
3. Require less administration time than the full CDI.
4. Avoid overuse of the same subset of items—particularly important in repeated measures with the same participants (e.g., in longitudinal studies).

In the following section we will explore the two CAT-CDI’s performance on each of those criteria.

Item selection in the two CAT-CDIs. It is to be expected that a CAT-CDI will not need to administer all the items in the item bank. In fact, in all the task administrations in the validation study the English CAT-CDI used 251 items (36.91%) and the Polish CAT-CDI used 258 items (38.74%). By design, a CAT-CDI selects the items that provide the most information for each participant. In practice, this means it draws from a subset of items that both match the participant’s current ability estimate in difficulty and show high discrimination, allowing clear distinctions between individuals with

similar ability levels. A potential concern, however, is that the CAT-CDI might repeatedly rely on the same subset of optimal items. CAT-CDI's usefulness in research—particularly in longitudinal studies—lies in the possibility of administering the CDI frequently without parents becoming overly familiar with specific, frequently repeated items. This advantage holds only if the CAT-CDI does not consistently present the same items across administrations. Therefore, we investigated whether the two CAT-CDIs repeatedly selected any items too frequently. In English, 3 items appeared in more than half of administrations - “*long*” in 64% of administrations, “*make*” in 54% of administrations, and “*last*” in 53% of administrations. As expected, they are also high discrimination items in their difficulty bins. “Long” is additionally one of the starting items, i.e. a first item shown to the parent, chosen so that there is high probability the parent can respond positively. In Polish, 3 items appeared in more than half of administrations - “*szukać*” (to look for) appearing in 83% of administrations, “*znaleźć*” (to find) appearing in 61% of administrations, and “*babcia*” (grandmother) appearing in 60% of administrations. As expected, all three items show very high discrimination. and “*Szukać*” (to look for) and “*znaleźć*” (to find) are in fact in top 5 discrimination items in general. “*Babcia*” (grandmother) is one of the starting items. The fact that only 3 items out of c.a. 250 (c.a. 1%) are used in more than half administrations is to CAT-CDI's advantage.

To check whether the CDI items common in both languages may show similar frequencies in CAT-CDI administrations, we ran Spearman's rank correlation and found that the items frequencies in administrations were weakly correlated, $r_s = .37$, $S = 6,420,909.29$, $p < .001$. However, the two CAT-CDIs differed in their potential length, as the English CAT-CDI was set to administer 25–50 items and the Polish CAT-CDI could administer up to 75 items (no minimum was set, but in practice the minimum items administered were 13). As an item is more likely to appear in longer tests (simply due to test length), then frequency of the Polish items could be inflated. *NOTE*: Could it be that, as an item is more likely to appear in longer tests (simply due to test length), frequency of

the Polish items could be inflated? Could it influence the item's rank? I could probably recalculate item frequency not per total number of administrations, but per total number of items administered? SEE ISSUE #3

CAT-CDIs' usefulness in research and practice

One of the key metrics for CAT-CDI's usefulness is whether it can shorten the CDI administration compared to the full CDI, but still obtain a reliable estimate of child's lexical ability. We have found that CAT-CDIs were significantly shorter to administer: the English CAT-CDI median time was 342s (~5.7 minutes) (median full CDI time was) and the Polish CAT-CDI median time was 117s (~1.95 minutes) (median full CDI time was 1240s (~20.67 minutes)). Even though the CAT-CDI in Polish seemed shorter (compared to English CAT-CDI), the number of items administered in the two language versions of CAT-CDI was comparable: English $M = 31.42$, $Mdn = 25$ (25–50 items), Polish $M = 34.71$, $Mdn = 23$ (13–75 items).

The two CAT-CDIs differed in their settings as to when to finish the administration. Specifically, the Polish CAT-CDI was set so that the SEM as low as 0.1 be reached (with as few items as possible), and if the SEM could not be lowered to or below 0.1, the CAT-CDI stopped after administering a maximum of 75 items. The English CAT-CDI on the other hand was set to administer a maximum of 50 items, but the administration could be stopped earlier if the SEM of 0.15 or lower was reached. In other words, the Polish CAT-CDI prioritized as low SEM as possible, while the English CAT-CDI prioritized shorter test length. This difference resulted in slightly lower mean SEM in Polish CAT-CDI, compared to English CAT-CDI $\Delta M = 0.06$, 95% CI [0.05, 0.07], $t(257.25) = 11.36$, $p < .001$ but comparable mean number of items administered, $\Delta M = -3.29$, 95% CI [-7.74, 1.16], $t(137.00) = -1.46$, $p = .147$.

Figure 3. Percentage of parents' consistency in responding to items in the two CDI versions in the same way (in the English and in the Polish dataset).

Parental consistency in responses

We compared the parental consistency in their responses in the full and CAT version of CDI in two ways - using a percentage of agreement and by calculating Cohen's Kappa, which additionally factors in chance agreement. When calculating the percentage agreement, for each parent we calculated the number of items to which they responded in the same way in both CDI versions against the whole number of items asked in both CDI versions. We found though the Median consistency was relatively high: 72% for English and 75% for Polish, it varied largely across parents in both samples (see Figure 3).

We also calculated Cohen's kappa per each parent, considering their observed agreement (between responses to the same items in full and CAT CDI) and expected agreement by chance. The kappa values indicated fair (or close to fair) agreement: English $M = 0.40$, $Mdn = 0.37$, Polish $M = 0.39$, $Mdn = 0.34$. *NOTE:* There's an Issue for that here

Discussion

It seems then that the relation between the two estimates differs, depending on the ability level: for lower abilities, the difference between the two estimates is most visible, with CAT-CDI estimates higher than the full CDI estimates. For higher ability, the difference decreases or even (as in the case of Polish) changes direction, with CAT-CDI estimates lower than the full CDI estimates.

In points for now:

1. *Strong correlations with full CDI.*

The CAT-CDIs were strongly correlated with the full CDI versions in both languages, which supports the overall validity of the CAT approach. These correlations held for both monolingual and multilingual participants. However, the Polish sample was small, so further research is needed—and planned—to confirm these findings.

2. *Cases of extreme divergence.*

CAT-CDI scores diverged notably from full CDI estimates for only a small number of children in both language groups. In the Polish sample all divergent cases had low SEM, and their full CDIs were unusually short—maybe the full form underestimated their ability? In the English sample, their full CDIs were not very short, but SEM was relatively low, which is good.

3. *Item parameters across languages.*

Item parameters (i.e., difficulty and discrimination) showed moderate correlations across languages. These likely stem from variations in the calibration samples. Still, some semantic categories showed consistent patterns across languages, suggesting underlying structural similarities in lexical development.

4. *Item selection.*

Each CAT version used c.a. half of the full CDI item pool. Few items were overused (mostly those with highest discrimination in the item pool or starting items). But we also saw items being chosen for CAT that wouldn't be considered very informative (i.e., of low discrimination). That's something to explore further, I wrote to Phil Chalmers (author of mirt and mirtCAT), maybe he'll be able to help?

5. *Efficiency and Reliability.*

CAT-CDIs were significantly shorter than the full CDIs while maintaining high reliability for most children. The few less reliable estimates were for children at the ends of the ability range (children with either very low or very high lexical skills). Comparing Polish and English samples, the ability ranges with low SEM differed (see Figure 3) - this again might be a result of the calibration samples and item parameters? This is a good place to stress the importance of well-balanced, diverse calibration datasets. Also, while the CAT-CDI is efficient and useful for screening or initial identification ("pomiar przesiewowy" in Polish), it may be less suited for diagnostic purposes where high precision is needed across the full ability range.
